Nonneutral network and the role of bargaining power in side payments

Eitan Altman, Manjesh Kumar Hanawal and Rajesh Sundaresan

***Abstract*—Representatives of several Internet access providers have expressed their wish to see a substantial change in the pricing policies of the Internet. In particular, they would like to see content providers pay for use of the network, given the large amount of resources they use. This would be in clear violation of the “network neutrality” principle that had characterized the development of the wireline Internet. Our first goal in this paper is to propose and study possible ways of implementing such payments and of regulating their amount. We introduce a model that includes the internaut’s behavior, the utilities of the ISP and of the content providers, and the monetary flow that involves the internauts, the ISP and content provider, and in particular, the content provider’s revenues from advertisements. We consider various game models and study the resulting equilibrium; they are all combinations of a noncooperative game (in which the service and content providers determine how much they will charge the internauts) with a cooperative one - the content provider and the service provider bargain with each other over payments to one another. We include in our model a possible asymmetric bargaining power which is represented by a parameter (that varies between zero to one). We also study two dynamic game models and study the convergence of prices to equilibrium value.**

***Index Terms*—network neutrality; bargaining; two-sided market; game theory; telecommunications policy; dynamics**

I. INTRODUCTION

The huge growth of the Internet and related electronic commerce and businesses was characterized by a neutral (egalitarian) policy for accessing the global Internet (i) for download or for using services, and (ii) for deploying services or uploading contents. This neutrality principle meant that packets could not be discriminated according to their origin or destination, the application, or the protocol they use.

Those opposing the neutrality argue that (i) some applications (such as peer to peer (P2P) streaming applications) require a lot of costly resources, and (ii) if a neutral policy is pursued, there would be no incentive for investing in the infrastructure of the network in order to upgrade it.

In a nonneutral net, discrimination of packets can mean a selective blocking of packets, selective throttling of flows (allocating less throughput to some flows), having exclusive agreements between the access provider and some content or service providers, and charging traffic in a discriminatory way. Blocking and throttling P2P traffic has been a common practice in several countries, and not just during congestion epochs [1]. In the USA, such a practice was criticized by the FCC telecom regulation body. See [2] and the references therein for a overview of current issues debated in net neutrality and various models proposed to study them.

There is one particular economic issue that is at the heart of the conflict over network neutrality. Hahn and Wallsten [3] write that net neutrality “usually means that broadband service providers charge consumers only once for Internet access, do not favor one content provider over another, and do not charge content providers for sending information over broadband lines to end users.” This motivated a study [1] of the implications of being nonneutral and of charging the content providers (CP). Using non-cooperative game theoretic tools, [1] showed that if one provider, say the internet service providers (ISP), has the power to impose payments on the other provider (the CP), not only does the content provider lose control over how much they can pay, the internauts suffer, and moreover, the ISP’s performance degrades. More precisely, [1] showed that the only possible equilibrium would be characterized by prices that will induce zero demand from the internauts. This phenomenon does not occur if the price that one provider is requested to pay to the other were fixed by some regulator. See also Njoroge et al. [4] for a study of multiple interconnected ISPs, a continuum of internauts and several CPs.

The sources of income (other than side payments between operators) in the model studied in [1] were payments of internauts (to both the ISP as well as the CP), and some third party payment (e.g. publicity income) that the content provider receives. Our objective in this paper is to study mechanisms for determining which provider should pay the other and how much. We are in particular interested in the impact of such mechanisms on the equilibrium. In this work we do not consider quality of service (QoS) aspects. But see [5] for an extension of our model to account for QoS and a study of how side payments are affected if internauts are more sensitive to price set by one of the providers.

The side payment from one provider to another is expected to be financed by income from internauts and from advertisers (publicity income). Cooperative game theory provides us with useful tools for designing revenue sharing mechanisms that possess some fairness properties. In [6]-[7] the Shapley value (which is known to have some fairness properties [8]) was used for deciding how revenues from internauts should be split between the service and the content providers.

Revenue sharing mechanisms were studied in [9] and [10].

The authors’ work on this paper was supported in part by each of the following projects: DAWN (Distributed Algorithms for Wireless Networks) an INRIA Associates program (http://www-sop.inria.fr/members/Eitan.Altman/), and the Indo-French Center for the Promotion of Advanced Research (under Project 4000 IT).

Eitan Altman and Manjesh Kumar Hanawal are with INRIA and are located at the University of Avignon. Rajesh Sundaresan is with the Department of Electrical Communication Engineering at the Indian Institute of Science, Bangalore 560012, India.

But our models are very different from theirs. While they assume smooth demand functions, this is not the case in our models. Furthermore, the two-sided pricing model of [10] does not allow the content providers to charge the customers directly, while our models do. A third difference is related to bargaining and timing of actions, as discussed next.

We shall focus in this paper on mechanisms based on the Nash bargaining paradigm (which is known in the network engineering context as the proportional fair assignment). It is the unique way of transferring utilities that satisfies a well known set of four axioms [11] related to fairness. We note that assigning the side payments fairly is just part of the story. In practice one provider may have more weight than the other one in the decision on the amount of side payment. We then say that the provider has a larger bargaining power (we shall make this precise in the next section). As an example, the Spanish ISP "Telefonica" announced on 8 February 2010 that it considered charging Google, indicating perhaps that the bargaining power of Google is weaker than that of Telefonica in the Spanish telecommunications market. Our work will allow to determine exactly how much payment would go from one provider to another as a function of the bargaining powers of each provider. For quantifying the bargaining power of each side, we follow the approach presented in [12].

Our goal in this paper is to understand a very simple and tractable model of a two player game with one agent being a content provider (CP) and another agent being an internet service provider (ISP). Several ancillary parties are also involved – the users who respond to prices via a demand function, advertisers who are providers of revenue, and an arbitrator who regulates the side payments taking into account the bargaining power of the players. In Section II we study the single-CP single-ISP game in two settings – bargaining before and after setting the prices. We then extend the results to the case when there are multiple content providers in Section III. The demand function we consider in Section II (single-CP case) is a simple, linear, decreasing function of the net price. In the multiple-CP case, demand for content from a CP is linear and decreasing in the price of that CP's content, but linear and increasing in the price of other CPs' contents, reminiscent of the Bertrand oligopoly [13]; see (8). In other words, demand for content from CP i is negatively correlated with the price of CP i content, but positively correlated with others' prices. This positive correlation may be anticipated as due to increased demand for CP i content as a consequence of increased capacity arising from decreased demand for CP j content on account of a CP j price increase. However, the positive correlation ceases as soon as the demand for content from a CP goes to zero, a generalization that extant literature does not consider. We examine the structure of the demand function in the general case in Section III-B, and then study the equilibria for bargaining before the actions and after the actions in subsequent sections (Sections III-D and III-E). In the multiple-CP case, due to combinatorial complexity, we give a complete characterization of all equilibria for the case of two CPs. We anticipate that the results will extend straightforwardly when there are more than two CPs. In Section IV, we study two dynamic models of the game studied in Section III and study their convergence. The paper concludes with a discussion in Section V and proofs of main results in the appendices.

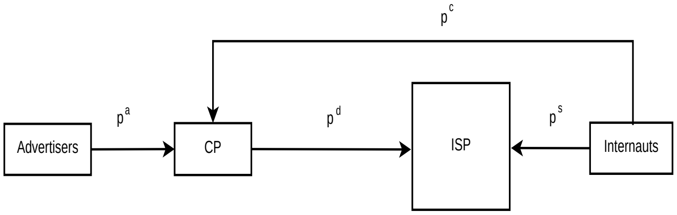

Fig. 1. Monetary flow in a nonneutral network.

II. THE CASE OF A SINGLE CP AND A SINGLE ISP

We first begin with the simple case of a single CP and a single ISP. All the internauts are connected to the ISP, and can access the content of the CP only through the ISP. See Figure 1 for a payment flow diagram. The various parameters of the network neutrality game are as follows.

Parameter	Description
p^s	Price per unit demand paid by the users to the ISP. This can be positive or negative.
p^c	Price per unit demand paid by the users to the CP. This too can be positive or negative.
$d(p^s, p^c)$	Demand as a function of prices. We shall take this to be $d(p^s, p^c) = [D_0 - \alpha(p^s + p^c)]_+$, where $[x]_+ = \max\{x, 0\}$ is the positive part of x.
p^a	Advertising revenue per unit demand, earned by the CP. This satisfies $p^a \geq 0$.
p^d	Price per demand paid by the CP to the ISP. This can be either positive or negative.
U_{ISP}	The revenue or utility of the ISP, given by $d(p^s, p^c)(p^s + p^d)$.
U_{CP}	The revenue or utility of the CP, given by $d(p^s, p^c)(p^c + p^a - p^d)$.
γ	Bargaining power of the ISP with respect to the CP. This satisfies $0 < \gamma < 1$.

We consider two interesting games. The timing for the first game is as follows.

- The ISP and the CP bargain over the payment p^d from the CP to the ISP. This can be positive or negative.
- The CP sets the price p^c. The ISP sets the price p^s. Both set their prices simultaneously.
- The internauts react to the prices and set the demand.

In the second game, bargaining is done later:

- The CP and the ISP set their respective access prices p^c and p^s simultaneously.
- The ISP and the CP bargain over the payment p^d from the CP to the ISP. This can be positive or negative.
- The internauts react to the prices and set the demand.

The first game arises when the charges per unit demand can change over a comparatively faster time-scale while the CP-ISP price changes over a slower time-scale. The second one is an interesting case that may arise in a regulatory setting where the prices per unit demand charged to the internauts varies over a slower time-scale, but the ISP and the CP can quickly renegotiate their prices. We analyze both models via backward induction and identify the equilibria.

For a fixed p^s and p^c, bargaining results in an agreement of a payment p^d from the CP to the ISP, determined by

$$p^{d*} \in \arg\max_{p^d} U_{\mathsf{ISP}}^{\gamma} \times U_{\mathsf{CP}}^{1-\gamma}.$$

The parameter γ determines the bargaining power of the ISP with respect to the CP. When p^{d*} is negative, the ISP is the one that makes a payment to the CP.

We now discuss some properties of the bargaining solution.

If we take $\gamma = 1/2$ then the maximization is equivalent to that of the product of the utilities of the ISP and the CP. This is then the standard Nash bargaining approach [11] for resource allocation, known in networking as the proportional fair allocation [14]. (It is known to be the unique assignment satisfying a set of four axioms.) To understand the case of general γ, consider first the problem of maximizing $U_{\mathsf{ISP}}^{m_1} U_{\mathsf{CP}}^{m_2}$ where m_1 and m_2 are integers. The form of the objective function suggests that we are simply searching for a standard proportional fairness solution but where there are m_1 ISP's and m_2 content providers[1]. Thus the ISP is said to have a bargaining power equivalent to that of m_1 players, and the CP equivalent to that of m_2 players. Finally, we note that $\arg\max(U_{ISP}^{m_1} U_{CP}^{m_2})$ is the same as that of $(U_{\mathsf{ISP}}^{\gamma} U_{\mathsf{CP}}^{1-\gamma})$ where $\gamma := m_1/(m_1+m_2)$.

We next observe that the game problem is equivalent to replacing all utilities by the log of the utilities. We may imagine that the bargaining is done by another player, the regulator, whose (log) utility equals

$$\overline{U}_{\mathsf{regulator}} := \gamma \overline{U}_{\mathsf{ISP}} + (1-\gamma)\overline{U}_{\mathsf{CP}}, \tag{1}$$

where $\overline{U}_{\mathsf{ISP}} = \log U_{\mathsf{ISP}}$ and $\overline{U}_{\mathsf{CP}} = \log U_{\mathsf{CP}}$. At least one previous work has already used as utilities the linear combination of performance measures of other players and interpreted γ as some measure of the "degree of cooperation", see [15], in other contexts.

Let us now return to our games. In the first game, the CP and the ISP bargain over Nash equilibria. In the second, they choose p^a and p^c knowing that they will bargain subsequently. A *summary of the results* for the single-CP single-ISP games are as follows.

1) In both cases, there exists a pure strategy Nash equilibrium, in a sense that will be made precise, with strictly positive demand and strictly positive utilities for the agents. In the pre-bargaining problem there are other zero-demand equilibria. In the post-bargaining problem, the aforementioned pure strategy Nash equilibrium is unique.

2) In all cases with strictly positive demand, users pay the ISP. But users pay the CP only if the advertising revenue is small. Otherwise the CP subsidizes the users.

3) If either of the agents have control over p^d, the equilibrium demand is zero. None of the parties benefit from this situation. On the contrary, if p^d is under the control of a disinterested arbitrator, there is an equilibrium where every one benefits. This is the key insight gained from our analysis, that some sort of regulation can bring benefits to all.

4) Interestingly, if the agents bargain beforehand and the strictly positive demand equilibrium ensues, the payments by the users and resulting utilities of all agents are independent of the actual value of p^d.

5) If the agents bargain beforehand, over Nash equilibria, then demand settles at a lower value than if the agents bargain after setting their prices.

6) If the agents bargain beforehand, they end up with equal revenues. If they bargain afterward, they share the net revenue in the proportion of their bargaining power.

7) Finally, if $\gamma \in \left[\frac{4}{9}, \frac{5}{9}\right]$, then both agents prefer to fight it out after setting their prices. For $\gamma > 5/9$, the ISP prefers post-arbitration, and for $\gamma < 4/9$, the CP prefers post-arbitration.

While the above appear to suggest that post-arbitration may prove to be good to the internauts, there are no pure-strategy Nash equilibria in the post-arbitration game when there are two or more CPs under a model where the demand for content from a CP is positively correlated with a competing CP's price. We shall return to this in a later section.

With these motivating remarks, we shall now proceed to state these claims in a precise fashion and to prove them. In subsequent sections we shall study the extension of the above results to the case of multiple CPs and to the case of an exclusive contract between one of the CPs and the ISP.

A. Bargaining over Nash equilibria

We first consider the case where the agents bargain over Nash equilibria. Both agents bargain over the choice of p^d, knowing that they will subsequently play a simultaneous action game where the ISP and CP will choose p^s and p^c, respectively. Our main result here is summarized as follows.

Theorem 1. *When the CP and the ISP bargain beforehand over Nash equilibria, we have the following complete characterization of all pure strategy Nash equilibria.*

(a) Among profiles with strictly positive demand, there is a unique pure strategy Nash equilibrium with the following properties:

- *The uniqueness is up to a free choice of p^d.*
- *At equilibrium, we have:*

$$p^s = \frac{D_0 + \alpha p^a}{3\alpha} - p^d, \tag{2}$$

$$p^c = \frac{D_0 - 2\alpha p^a}{3\alpha} + p^d. \tag{3}$$

- *The net user payment per demand $p^s + p^c$ is unique and is given by*

$$p^s + p^c = \frac{2D_0 - \alpha p^a}{3\alpha}.$$

  Any p^d paid by the CP is collected from the user and further returned back to the user by the ISP.
- *The demand is unique and is given by $(D_0 + \alpha p^a)/3 > 0$.*

---

[1] The optimization problem involved in computing the proportional fair solutions, that of maximizing the product of utilities, may have some constraints. We do not modify the constraints when altering m_1 or m_2. The change in m_1 or m_2 merely corresponds to a re-weighting of the utilities and not of addition or removal of users.

- *The utilities of the ISP and CP are equal and given by*

$$U_{\mathsf{ISP}} = U_{\mathsf{CP}} = \frac{(D_0 + \alpha p^a)^2}{9\alpha}.$$

(b) For each choice of p^d, a strategy profile (p^s, p^c) constitutes a Nash equilibrium with zero demand if and only if the following two inequalities hold:

$$\begin{aligned} p^s &\geq D_0/\alpha + p^a - p^d, && (4)\\ p^c &\geq D_0/\alpha + p^d. && (5) \end{aligned}$$

Proof: We first observe that at equilibrium, U_{ISP} and U_{CP} are both nonnegative. If not, the ISP (resp. CP) has strictly negative utility. He can raise the price p^s (resp. p^c) to a sufficiently high value so that demand becomes zero, and therefore $U_{\mathsf{ISP}} = 0$ (resp. $U_{\mathsf{CP}} = 0$). Thus a deviation yields a strict increase in utility and therefore cannot be an equilibrium. It follows that at equilibrium, we may take the revenues per demand for the ISP and CP to be nonnegative, i.e., $p^s + p^d \geq 0$, and $p^c + p^a - p^d \geq 0$.

We next deduce (b), which is a characterization of all the pure strategy NE with zero demand. Consider a fixed p^d. If a pair (p^s, p^c) were an equilibrium with zero demand, then clearly

$$D_0 \leq \alpha(p^s + p^c),$$

and

$$U_{\mathsf{ISP}} = d(p^s, p^c) \times (p^s + p^d) = 0.$$

Moreover, the ISP should not be able to make his utility positive, i.e., any p^s that makes demand strictly positive, $p^s < D_0/\alpha - p^c$, must also render price per unit demand zero or negative, $p^s + p^d \leq 0$. This can happen only if $(D_0/\alpha - p^c) + p^d \leq 0$ which is the same as (5). Similarly, the CP should not be able to make his utility positive, i.e., any p^c that makes demand strictly positive, $p^c < D_0/\alpha - p^s$, must render CP price per unit demand nonpositive, $p^c + p^a - p^d \leq 0$. This can happen only if $(D_0/\alpha - p^s) + p^a - p^d \leq 0$ which is the same as (4). This proves the necessity of (4) and (5). We now show sufficiency. Let (4) and (5) hold. Then addition of p^c to both sides of (4) and some rearrangement yields

$$p^c + p^a - p^d \leq p^s + p^c - D_0/\alpha. \qquad (6)$$

Since the left side is the revenue per unit demand for the CP, it must be nonnegative, and hence $p^s + p^c - D_0/\alpha \geq 0$, which upon rearrangement yields $D_0 - \alpha(p^s + p^c) \leq 0$. The demand $d(p^s, p^c)$ is therefore zero. Let us now consider a deviation by the CP for a fixed ISP price p^s that satisfies (4). We will show that the least deviation (decrease in price) that sets the demand at the threshold of positivity results in a negative revenue per demand for the CP. Indeed, this critical price q^c that sets the demand at the threshold of positivity satisfies the equation

$$D_0 - \alpha(q^c + p^s) = 0.$$

Again, addition of q^c to both sides of (4) yields, by the same steps above that led to (6),

$$q^c + p^a - p^d \leq p^s + q^c - D_0/\alpha = 0.$$

Further reduction in price to make demand strictly positive only results in negative revenue and negative utility. Consequently, the CP does not have a deviation that yields a higher revenue. A similar argument shows that, under (5), the ISP can make demand strictly positive only if its revenue is negative. It too does not have a deviation with a strictly greater utility. Thus (4) and (5) constitute zero demand equilibrium prices.

Let us now search for an equilibrium with a strictly positive demand. Such a (p^s, p^c) must lie in the interior of the set of all pairs satisfying $D_0 \geq \alpha(p^s + p^c)$. As U_{ISP} is concave in p^s for a fixed p^c and p^d, whenever the utility is strictly positive, we must have a local maximum at equilibrium, i.e.,

$$\begin{aligned} \frac{\partial U_{\mathsf{ISP}}}{\partial p^s} &= \frac{\partial}{\partial p^s}(D_0 - \alpha(p^s + p^c))(p^s + p^d)\\ &= D_0 - \alpha p^s - \alpha p^c - \alpha(p^s + p^d)\\ &= 0, \end{aligned}$$

which yields

$$p^s = \frac{D_0 - \alpha p^c - \alpha p^d}{2\alpha}.$$

Analogously, U_{CP} is concave in p^c for fixed p^s and p^d wherever the function is positive, and so the equilibrium p^c should be a local maximum, i.e.,

$$\begin{aligned} \frac{\partial U_{\mathsf{CP}}}{\partial p^s} &= \frac{\partial}{\partial p^s}(D_0 - \alpha(p^s + p^c))(p^c + p^a - p^d)\\ &= D_0 - \alpha p^s - \alpha p^c - \alpha(p^c + p^a - p^d)\\ &= 0, \end{aligned}$$

which yields

$$p^c = \frac{D_0 - \alpha p^s - \alpha(p^a - p^d)}{2\alpha}.$$

Solving these two simultaneous equations in the variables p^s and p^c, we see that p^s and p^c are given by (2) and (3), respectively. Note that the choice of p^d is free. Once this is chosen, the choice fixes both p^s and p^c. This proves the second bullet. We shall return to prove the first bullet after proving the others.

Adding these two, we see that $p^s + p^c$ is a constant for any such equilibrium. Choice of p^d fixes both p^s and p^c. This is true for any Nash equilibrium with a strictly positive demand. Furthermore, any p^d that is paid reduces p^s by that amount and increases p^c by the same amount. This proves the third bullet.

The last two bullets follow by direct substitutions into $d(p^s, p^c)$, U_{ISP}, and U_{CP}.

As a consequence of the observation that $U_{\mathsf{ISP}} = U_{\mathsf{CP}}$ at any equilibrium regardless of the value of p^d, we have

$$U_{\mathsf{ISP}}^{\gamma} \times U_{\mathsf{CP}}^{1-\gamma}$$

is independent of p^d at any equilibrium, for any fixed bargaining power $\gamma \in (0, 1)$. The arbitrator may thus pick any p^d. This proves the first bullet. (This observation holds even for zero-demand equilibria). The proof is now complete. ■

Remarks: 1) Every choice of p^d can also result in the undesirable zero-demand equilibria, and not just the desirable equilibrium with strictly positive demand.

2) For this strictly positive demand equilibrium, the natural choices of p^d are those that make $p^d = 0$, i.e., there is no payment from CP to ISP, or $p^c = 0$, there is no payment from the user to the CP, or $p^s = 0$, there is no payment from the user to the ISP.

3) If one places the additional restriction that $p^s \geq 0$, the only effect of this constraint is that the choice of p^d is restricted to $p^d \leq (D_0 + \alpha p^a)/(3\alpha)$, and the above theorem continues to hold.

4) It is easily seen that if p^d is controlled by either agent, the only equilibria fall amongst the deadlocking zero demand points. Thus bargaining beforehand induces a good equilibrium point.

B. Bargaining after actions

We next consider the case when the CP and ISP decide on their respective prices first, knowing that they will subsequently bargain over p^d, say in the presence of the arbitrator.

Theorem 2. *When the CP and the ISP set prices simultaneously before agreeing on p^d and then bargain in the presence of an arbitrator, there is a unique pure strategy Nash equilibrium with the following properties:*

- *The uniqueness is up to a free choice of either p^s or p^c. Without loss of generality, we may assume a free p^s.*
- *At equilibrium, the net user payment per demand is uniquely given by*

$$p^s + p^c = \frac{D_0 - \alpha p^a}{2\alpha}.$$

- *The demand is unique and is given by $(D_0+\alpha p^a)/2 > 0$.*
- *The arbitrator will set p^d so that the net revenue per demand $p^s+p^c+p^a = \frac{D_0+\alpha p^a}{2\alpha}$ is shared in the proportion γ and $1-\gamma$ by the ISP and the CP, respectively.*

Proof: As in the previous section, it is clear that the revenues per demand and the utilities for both agents are nonnegative. If this is not the case, the aggrieved CP or the ISP guarantees himself a strictly larger zero utility by raising the price under his control so that demand reduces to 0.

Let us now perform a search for equilibria with strictly positive demand. Such a (p^s, p^c) is an interior point among all those pairs that satisfy $D_0 - \alpha(p^s + p^c) \geq 0$. Consider a fixed interior point (p^s, p^s). The arbitrator sets p^d to

$$\begin{aligned} &\arg\max_{p^d} U_{\mathsf{ISP}}^{\gamma} \times U_{\mathsf{CP}}^{1-\gamma} \\ &\quad = \arg\max_{p^d} \left[\gamma \log(p^s + p^d) + (1-\gamma)\log(p^c + p^a - p^d)\right], \end{aligned}$$

where the equality follows because the demand can be pulled out of the optimization. The optimization is over the set of p^d that ensure that the arguments inside the logarithm remain strictly positive. It is easy to see that the latter function is concave in p^d, and thus the maximizing p^d satisfies

$$\frac{\gamma}{p^s + p^d} - \frac{1-\gamma}{p^c + p^a - p^d} = 0,$$

which yields $p^d = \gamma(p^c + p^a) - (1-\gamma)p^s$.

Substitution of this p^d yields

$$\begin{aligned} p^s + p^d &= \gamma(p^s + p^c + p^a) \\ p^c + p^a - p^d &= (1-\gamma)(p^s + p^c + p^a). \end{aligned}$$

Clearly, $p^s + p^c + p^a$ is the net revenue per demand for both ISP and CP put together, and the ISP and the CP share this booty in the fraction of their bargaining powers.

Knowing this action of the arbitrator, the ISP will respond optimally to a CP's p^c by maximizing

$$U_{\mathsf{ISP}} = d(p^s, p^c)(p^s+p^d) = (D_0 - \alpha(p^s+p^c) \times \gamma(p^s+p^c+p^a).$$

This is a concave function of p^s, and the maximum is at

$$p^s = \frac{D_0 - \alpha p^a}{2\alpha} - p^c. \tag{7}$$

Similarly, for an ISP's p^s, the CP's best response is

$$p^c = \frac{D_0 - \alpha p^a}{2\alpha} - p^s,$$

which is the same equation as (7).

At equilibrium, we thus have $p^s + p^c$ uniquely determined and given by the second bullet. A substitution yields that the demand is given by

$$d(p^s, p^c) = D_0 - \alpha(p^s + p^c) = \frac{D_0 + \alpha p^a}{2},$$

which proves the third bullet.

The revenue per demand is easily seen to be $(D_0 + \alpha p^a)/(2\alpha)$. Further substitution yields that net revenue is

$$d(p^s, p^c)(p^s + p^c + p^a) = (D_0 + \alpha p^a)^2/(4\alpha),$$

a strictly positive quantity shared in proportion of the bargaining powers by the ISP and CP. This proves the last bullet.

Finally, for any p^s, the arbitrator will set p^d to ensure this proportion, and thus p^s may be taken as a free variable. Each p^s and p^c satisfying the above conditions is a Nash equilibrium. This proves the first bullet.

Finally, it still remains to prove that there is no zero-demand equilibrium. Suppose that (p^s, p^c) is such that we get a zero-demand, i.e., $D_0 \leq \alpha(p^s + p^c)$. With $\varepsilon = (D_0 + \alpha p^a)/2 > 0$, the ISP can set his new price to

$$q^s = D_0/\alpha - p^c - \varepsilon/\alpha$$

yielding a demand $D_0 - \alpha(q^s + p^c) = \varepsilon > 0$ and a revenue

$$\gamma(q^s + p^c + p^a) = \gamma(D_0/\alpha - \varepsilon/\alpha + p^a) = \gamma\varepsilon/\alpha > 0,$$

and therefore a strictly positive utility. A unilateral deviation yields the ISP a strict increase in his utility. Thus a (p^s, p^c) with zero demand cannot be a pure-strategy equilibrium. This concludes the proof. ■

Remarks: 1) The equilibrium utility for the ISP under post-bargaining is easily seen to be $9\gamma/4$ fraction of that under pre-bargaining. Clearly then, post-bargaining is favourable if $\gamma \geq 4/9$.

2) Similarly, the equilibrium utility for the CP under post-bargaining is $9(1-\gamma)/4$ fraction of that under pre-bargaining. The CP prefers post-bargaining if $1 - \gamma \geq 4/9$ or $\gamma \leq 5/9$.

3) Thus, if $\gamma \in \left[\frac{4}{9}, \frac{5}{9}\right]$, both will prefer post-bargaining. For $\gamma > 5/9$, ISP prefers post-bargaining while CP prefers pre-bargaining. Opposite is the case when $\gamma < 4/9$.

III. THE CASE OF MULTIPLE CPS

We now consider the case when there are several content providers. Internauts connect to each of the content providers through the single ISP. See Figure 2. The parameters of this game are given in the table that follows.

Parameter	Description
n	Number of content providers.
p_i^s	Price per unit demand paid by the users to the ISP for connection to CP i. This can be positive or negative.
p_i^c	Price per unit demand paid by the users to CP i. This too can be positive or negative.
p_i^a	Advertising revenue per unit demand, earned by the CP. This satisfies $p_i^a \geq 0$.
p_i^d	Price per demand paid by the CP to the ISP. This can be either positive or negative.
p^x	Vectors of aforementioned prices, where x is one of $s,\ c,\ a,\ d$.
$d_i(p^s, p^c)$	Demand for CP i as a function of the prices. See (8) below and the following discussion.
$r_{\mathsf{CP},i}$	The revenue per unit demand of CP i, given by $p_i^c + p_i^a - p_i^d$.
$r_{\mathsf{ISP},i}$	The revenue per unit demand of ISP coming from content provided by CP i, given by $p_i^s + p_i^d$.
U_{ISP}	The revenue or utility of the ISP, given by $\sum_i d_i(p^s, p^c)(p_i^s + p_i^d)$.
$U_{\mathsf{CP},i}$	The revenue or utility of the CP, given by $d_i(p^s, p^c)(p_i^c + p_i^a - p_i^d)$.
γ_i	Bargaining power of the ISP with respect to the CP.

A. *Demand function: Strictly positive demands*

The demand function for content from CP i is such that it depends on p^s and p^c only through the sum $p^s + p^c$, the vector of net payment per unit demand from the internauts. An interesting feature we wish to model is a *positive correlation in demand with respect to others' prices*. If CP i and ISP increase their prices for content from CP i, demand for this content naturally goes down. On the other hand, when the price for CP j content increases, where $j \neq i$, the decrease in demand for content from CP j frees up some capacity. This provides a marginally better delay experience for the internauts of other CPs, and particularly internauts of CP i. This positive effect creates a marginal increase in the demand for content from the other CPs, and in particular, an increase in the demand for content from CP i. We model this correlation effect by setting the demand functions to be

$$d_i(p^s, p^c) = \left[D_0 - \alpha(p_i^s + p_i^c) + \beta \sum_{j:j\neq i} (p_j^s + p_j^c) \right] \quad (8)$$

provided each of the demands are strictly positive. Here β is the sensitivity parameter for the increase in demand for CP i content per unit increase in price of CP j content, when $j \neq i$.

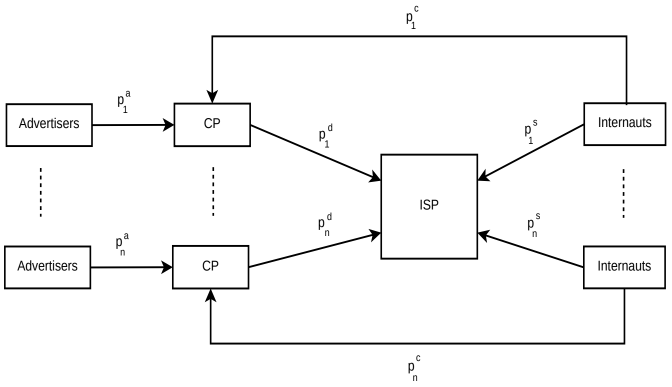

Fig. 2. Monetary flow in a nonneutral network with multiple CPs.

While (8) is justifiable when all demands are positive, further thought suggests that it must be refined a little to account for the following. When the price $p_i^s + p_i^c$ charged to CP i internauts is such that it forces demand d_i to be zero, then any additional increase in $p_i^s + p_i^c$ simply continues to hold this demand d_i at zero. The capacity freeing and the consequent phenomenon of increase in demand for other CPs' contents no longer occurs, and additional price rise for CP i content will have no further tangible effect on other internauts' behavior. We shall return to this refinement shortly after addressing some points on the positive demand case.

Let the evaluations in (8) be strictly positive for each i. If this is placed as a requirement, one could view it as a joint constraint on the actions of the ISP and CPs: given the other prices, CP i will not set too high a price that makes d_i zero; neither will the ISP. We may write $d_i(p^s, p^c) > 0$ for every i as

$$D_0 - \alpha(p_i^s + p_i^c) + \beta \sum_{j:j\neq i} (p_j^s + p_j^c) > 0, \ \ i = 1, \ldots, n, \quad (9)$$

which is compactly summarized as follows. Define the matrix $A = (\alpha + \beta)I_n - \beta J_n$ where I_n is the identity matrix of size $n \times n$, and J_n is the square matrix with all-one entries of size $n \times n$. The matrix A has diagonal entries α and all off-diagonal entries $-\beta$. Also define E_n to be the all-one vector of size $n \times 1$. Then the constraint (9) in matrix notation is

$$D_0 E_n - A(p^s + p^c) > 0. \quad (10)$$

Sum up the components in (9) over all i and set the sum price $P = \sum_i (p_i^s + p_i^c)$, and we see that the total demand is

$$nD_0 - (\alpha - (n-1)\beta)P$$

under the assumption that each d_i is strictly positive. For this total demand to be negatively correlated with the average price per unit demand P/n, we must have that

$$(n-1)\beta \leq \alpha, \quad (11)$$

an assumption that we make from now on. As before we assume that p_i^s and p_i^c can be negative, i.e., the ISP and CP can pay the internauts for their usage, with a consequent increase in demand.

It is a simple matter to verify that U_{ISP} given by

$$U_{\mathsf{ISP}} = \sum_{i=1}^{n} d_i(p^s, p^c)(p_i^s + p_i^d)$$

is a concave quadratic function of the vector of service provider prices p^s, under the constraint (9). Indeed, simple calculations show that the Hessian matrix is $-2A$. Matrices of this form arise quite often in the sequel. To see that this Hessian matrix is negative semidefinite, observe that

$$-2A = -2\alpha \times [(1-\rho)I_n + \rho J_n]$$

where $\rho = -\beta/\alpha$. The matrix $(1-\rho)I_n + \rho J_n$ has $1-\rho$ as an eigenvalue repeated $n-1$ times and $1+\rho(n-1)$ once, and is therefore positive semidefinite by our assumption (11). (It is positive definite if there is strict inequality in (11)). Consequently, the Hessian $-2A$ is negative semidefinite, and U_{ISP} is a concave function of p^s.

B. General demand function

As alluded to above, the demands in (8) have to be refined to account for the lack of further positive correlation after a demand reaches zero. See the discussion in the paragraph following the one containing (8). With a suitable reindexing, we may assume that the vector $p = p^s + p^c$ has components in the increasing order, i.e., $p_1 \leq p_2 \leq \cdots \leq p_n$, where $p_i = p_i^s + p_i^c$. For brevity, we shall abuse notation and refer to $d_i(p^s, p^c)$ as $d_i(p)$. Common sense suggests that if demand for CP i content is zero, then demand for CP j content for a $j \geq i$ must also be zero since its price is higher. It will be illuminating to study the evolution of the demand function as the price vector increases from the all-zero vector to p via $\min\{xE_n, p\}$, where x is a scalar parameter that increases from 0 to $+\infty$ and the $\min$ operation is taken component-wise.

For $x \in [0, p_1]$, we have $\min\{xE_n, p\} = xE_n$; all internauts are charged the same (net) price of x per unit demand. It is then immediate that all demands are equal, and from (8), this value is strictly positive if and only if

$$x < \frac{D_0}{\alpha - (n-1)\beta}.$$

In particular, demand for CP 1 is strictly positive at $x = p_1$ if and only if

$$p_1 < \frac{D_0}{\alpha - (n-1)\beta} =: T(1). \tag{12}$$

If (12) does not hold, the demand for the cheapest content is zero, and our common sense conclusion suggests that all other demands are also zero. If (12) holds, then at $x = p_1$, demand for CP 1 is strictly positive. For $x \in [0, p_1)$, the demand d_1 for content from CP 1 decreased with x. But further increase in x leaves the price for CP 1 content unchanged at p_1, and our observations about positive correlation with respect to others' prices indicates that d_1 must now begin to linearly increase with x for $x > p_1$. This is illustrated in Figure 3. Thus for $x \in [p_1, p_2]$, we see

$$\begin{aligned} d_1 &= D_0 - \alpha p_1 + (n-1)\beta x, \text{ for CP } 1 \\ d_i &= D_0 - (\alpha - (n-2)\beta)x + \beta p_1, \text{ for CP } i \geq 2. \end{aligned} \tag{13}$$

At $x = p_2$, the demand from CP 2, given by (13) for $i = 2$, is positive if and only if

$$p_2 < \frac{D_0 + \beta p_1}{\alpha - (n-2)\beta} =: T(2). \tag{14}$$

When (14) holds, d_1 is linear in x with positive slope $(n-1)\beta$ for x up to p_2, and all other d_i are linear and decreasing in x with negative slope $-(\alpha - (n-2)\beta)$. Again see Figure 3. If (14) does not hold, $d_i = 0$ for $i \geq 2$, but d_1 is set up to the value $D_0 - \alpha p_1 + (n-1)\beta x^*$ where $x^* = T(2)$. All demands are thus set in this latter case. If (14) holds, the former case, then one proceeds further in a similar fashion until $x^* = p_n$ and all demands are set, or until $x^* \in (p_{k^*}, p_{k^*+1}]$ for some k^*, when demands $d_j = 0$ for all $j \geq k^*$, and demands d_i are set with prices $\min\{x^* E_n, p\}$. To get an explicit expression for the demands, let us define

$$T(k) := \frac{D_0 + \beta \sum_{j:j<k} p_j}{\alpha - (n-k)\beta}, \quad k = 1, 2, \ldots, n. \tag{15}$$

Let k^* be the smallest index among $k = 0, 1, \ldots, n$ for which

$$\begin{aligned} p_i &< T(i), \quad i = 1, \ldots, k \\ p_{k+1} &\geq T(k+1). \end{aligned} \tag{16}$$

To further clarify (16), if $p_1 \geq T(1)$ then $k^* = 0$; if $p_i < T(i)$ for $i = 1, \ldots, n$, then $k^* = n$. In all other cases, the definition in (16) is unambiguous. Straightforward manipulations show that

$$T(k) > T(k+1) \text{ if and only if } p_k < T(k), \ k = 1, \ldots, n-1.$$

It follows from the definition of k^* that

$$T(1) > T(2) > \cdots > T(k^*) > T(k^*+1) \leq T(k^*+2), \tag{17}$$

where the last two inequalities hold if the corresponding indices are between 1 and n. Let us now get back to identifying the demands. Given k^*, we set x^* such that

$$D_0 - \alpha x^* + \beta \sum_{j<k^*+1} p_j + \beta(n-k^*-1)x^* = 0;$$

the solution is $x^* = T(k^*+1)$. The demands are now specified by

$$d_i(p) = \begin{cases} D_0 - \alpha p_i + \beta \displaystyle\sum_{j<k^*+1, j \neq i} p_j + (n-k^*)\beta T(k^*+1) & \\ & i = 1, \ldots, k^* \\ 0, & i > k^*. \end{cases} \tag{18}$$

This describes the behavior of the internauts for any given price vector $p = p^s + p^c$ and models the positive correlation of demand with other internauts' prices. Figure 3 depicts the procedure outlined above to evaluate the demands when there are $n = 3$ CPs. The other parameters are $D_0 = 100$, $\alpha = 10$, $\beta = 2$, and the price vector $p = (5, 10, 20)$. The slope of demand functions in different intervals are also marked. Here $k^* = 2$. The demand of each CP is obtained by noting the respective value of their demand curve at $x^* = T(3)$.

Let us now summarize the demands as a function of internaut prices ($p = p^s + p^c = (p_1, p_2)$) for the case when

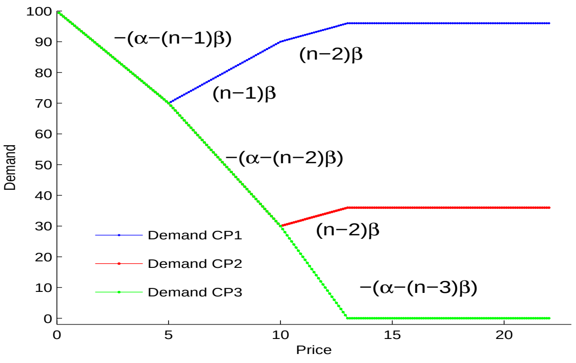

Fig. 3. Demand functions

$n = 2$. See Figure 4. As shown, we can divide the set of prices into four regions. A description of the regions is given below.

- Denote the vector of net prices by $p = (p_1, p_2)$. If it lies in the interior of the region bounded by lines AO and BO, denoted as Region 1, demands for contents from both the CPs are strictly positive.
- In the rectangular region enclosed between lines OC and OD, denoted as Region 2, the demands for contents from both CPs are zero.
- In the region enclosed between the lines AO and OC, denoted as Region 3, demand of CP 1 content is zero and that of CP 2 content is positive. Any point p that lies on the line AO is such that $p_1 = (D_0 + \beta p_2)/\alpha$ with $p_2 < D_0/(\alpha - \beta)$.
- In the region enclosed between the lines BO and OD, denoted as Region 4, demand of CP 2 content is zero and that of CP 1 is positive. Any point p that lies on line BO is such that $p_2 = (D_0 + \beta p_1)/\alpha$ with $p_1 < D_0/(\alpha - \beta)$.

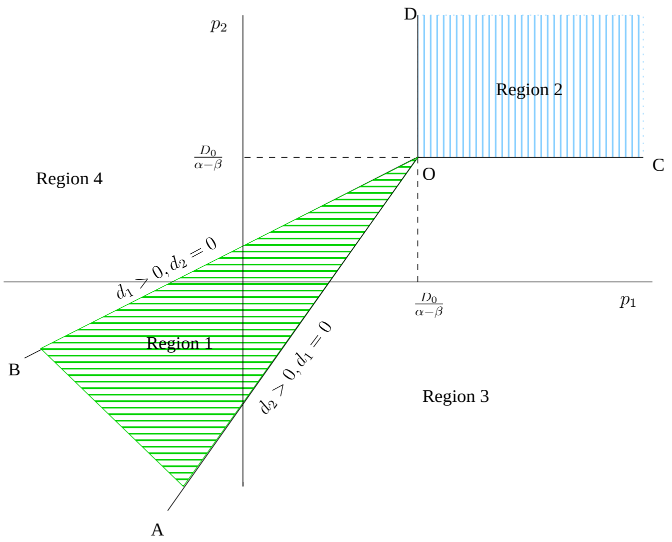

Fig. 4. Characterization of the demand region

C. *Timing of actions*

The timing of actions for the games are indicated as follows. For bargaining over Nash equilibria, the following is the action sequence.

- The ISP bargains with each of the CPs, separately and simultaneously, over the payment p^d from the CP to the ISP. This can be positive or negative. In bargaining with CP i, the ISP shall bring only that revenue into consideration which is generated by internauts connected to CP i.
- All the CPs choose their price p_i^c. The ISP chooses the vector p^s. All these actions are taken simultaneously.
- The internauts react to the prices and set their demands as per the discussion in the previous subsection.

As before, bargaining comes later in the second game, and the new sequence of actions is as follows.

- The CP and the ISP set their respective access prices p_i^c and p^s simultaneously.
- The ISP and each of the CPs bargain over the payment p_i^d from the CP to the ISP. This can be positive or negative. Yet again, the ISP shall be able to bring only that revenue into consideration which is generated by internauts connected to CP i.
- The internauts react to the set prices and set their demands.

The case when $\beta = 0$ is easily handled in either scenario. The actions of the various CPs (prices) do not influence each other. Though the ISP's utility is the sum over all revenues accrued from access to each CP, in bargaining with CP i, only the revenue generated by accesses to content of CP i matters. The ISP's utility is thus separable, and the problem separates into n single-CP single-ISP problems. The results of Theorems 1 and 2 immediately extend to this case. We shall henceforth assume that $\beta > 0$.

D. *Bargaining over Nash equilibria*

In this subsection, the CPs and the ISP bargain over Nash equilibria. We divide the presentation in this subsection into three parts. In the first part, we characterize all equilibria with all demands being strictly positive. In the second part, we characterize all equilibria with all demands being zero. In the third part, due to combinatorial complexity reasons, we restrict attention to two CPs ($n = 2$) and characterize all equilibria where demand for one CP's content is strictly positive and demand for the other CP's content is zero.

1) Equilibria with all demands strictly positive: We now characterize all equilibria where all demands take strictly positive values. Recall the definition of the matrix A and the vector E_n, given after (9). The matrix A has diagonal entries α and off-diagonal entries $-\beta$. E_n is the $n \times 1$ vector of all 1s.

Theorem 3. *Assume $\alpha > (n-1)\beta > 0$ and consider the case when the CPs and the ISP bargain beforehand. Among profiles with strictly positive demand, a strictly positive pure strategy Nash equilibrium exists if and only if the matrix $(A + 2\alpha I_n)^{-1}[D_0 E_n + A p^a]$ is made of strictly positive entries.*

When this condition holds, the pure strategy Nash equilibria have the following properties.

- *The uniqueness is up to a free choice of the vector p^d.*
- *At equilibrium, for each i, there exist constants g_i and h_i that depend only on $p^a,\ D_0,\ \alpha,\ \beta$ such that*

$$\begin{aligned} p_i^s &= g_i - p_i^d \\ p_i^c &= h_i + p_i^d. \end{aligned}$$

- *For each CP i, the net internaut payment per unit demand is unique and is given by $p_i^s + p_i^c = g_i + h_i$. Any payment p_i^d paid by CP i is collected from the internaut, and this in turn is returned to the internaut by the ISP.*
- *The demand vector is unique and does not depend on p^d.*
- *The revenues per unit demand, and therefore the total revenues collected by the CPs and the ISP, does not depend on p^d.*

Proof: The recipe for the proof is identical to that of Theorem 2, only with some matrix algebra. See Appendix A. ■

Remarks: 1) Yet again we notice that the actual choice of p^d does not affect the net cost per unit demand to the internauts; neither does it affect the equilibrium demand. It merely affects the way in which the payment by internaut is split between CP i and ISP. The mere fact that they agreed on an *arbitrary* p^d suffices to get an equilibrium more favorable than the case when p^d is under the control of one of the players.

2) For concreteness, we give the specific results for the case when $n = 2$; see (36) in Appendix A. Let $\tau = \beta/\alpha$. The negative definiteness condition is then $\tau < 1$, and thus $\tau \in (0, 1)$. The equilibrium prices turn out to be

$$\begin{aligned} p^s &= -p^d + \frac{1}{3(1-\tau^2/9)} \begin{bmatrix} 1 & \tau/3 \\ \tau/3 & 1 \end{bmatrix} p^a \\ &\quad + \frac{D_0}{3\alpha(1-\tau)(1-\tau/3)} E_2, \qquad (19) \\ p^c &= p^d - \frac{2}{3(1-\tau^2/9)} \begin{bmatrix} 1 & \tau/3 \\ \tau/3 & 1 \end{bmatrix} p^a \\ &\quad + \frac{D_0}{3\alpha(1-\tau/3)} E_2. \qquad (20) \end{aligned}$$

An interesting observation from (19) is that when $\tau \lesssim 1$, any increase in CP 2 price causes a reduction in demand for that content, but results in nearly similar in magnitude increase in demand for content 1, and vice-versa. The ISP resources thus remain nearly fully utilized which encourages the ISP to charge a high price, as evidenced by the appearance of $1 - \tau$ in the denominators for p^s. The prices charged by the CPs in (20) remain bounded.

2) Equilibria with all demands being zero: We now study the case of equilibria with all demands being zero. Obviously (12) must not hold; additional conditions are also needed.

Theorem 4. *A price vector (p^s, p^c) is an equilibrium with all demands being zero if and only if the following conditions hold for all $i = 1, 2, \ldots, n$:*

$$p_i^s \ \geq\ \frac{D_0}{\alpha - (n-1)\beta} + p_i^a - p_i^d \qquad (21)$$

$$p_i^c \ \geq\ \frac{D_0}{\alpha - (n-1)\beta} + p_i^d. \qquad (22)$$

Proof: See Appendix B. ■

Remarks: 1. Equations (22) and (21) are the same as saying that revenues per unit demand due to CP i content, to CP i and to the ISP, are at least $\frac{D_0}{\alpha-(n-1)\beta} + p_i^a = T(1) + p_i^a$, and this holds for each i. In such a case, all the CPs and the ISP are charging too high a price resulting in a deadlock equilibrium with all demands zero.

2. When $n = 1$, (21) and (22) reduce to (4) and (5), as they should.

3) Equilibria with mixed demands with $n = 2$: In order to avoid combinatorial complexities, and for ease of exposition, we focus on the case when $n = 2$ and now characterize all equilibria where demand for one content is strictly positive and demand for the other is zero.

Theorem 5. *(a) A price profile $((p_1^s, p_2^s), p_1^c, p_2^c)$ is an equilibrium with $d_1 > 0$ and $d_2 = 0$ if and only if*

$$\begin{aligned} p_1^s &= \frac{D_0' + \alpha' p_1^a}{3\alpha'} - p_1^d && (23) \\ p_1^c &= \frac{D_0' - 2\alpha' p_1^a}{3\alpha'} + p_1^d && (24) \\ p_2^s &\geq \frac{D_0 + \beta(p_1^s + p_1^c)}{\alpha} - p_2^d + p_2^a && (25) \\ p_2^c &\geq \frac{D_0 + \beta(p_1^s + p_1^c)}{\alpha} - p_2^s, && (26) \end{aligned}$$

where $D_0' = D_0(\alpha+\beta)/\alpha$ and $\alpha' = (\alpha^2 - \beta^2)/\alpha$.

(b) A price profile $((p_1^s, p_2^s), p_1^c, p_2^c)$ is an equilibrium with $d_2 > 0$ and $d_1 = 0$ if and only if the same conditions as above hold with indices 1 and 2 interchanged.

Proof: See Appendix C. ■

Remarks: 1) Region 1 equilibria are characterized in Theorem 3. Region 2 equilibria are characterized in Theorem 4. Equilibria in Regions 3 and 4 are characterized in Theorem 5. We have therefore characterized all equilibria in the $n = 2$ case.

2) Conditions (23) and (24) together constitute an equilibrium in case of a single CP with D_0 and α replaced by D_0' and α', respectively.

3) Conditions (25) and (26) may be interpreted as

$$r_{\mathsf{ISP},2} \geq T(2) + p_2^a \text{ and } p_2 \geq T(2)$$

where $r_{\mathsf{ISP},2} = p_2^s + p_2^d$ is the revenue to the ISP from CP 2 content.

E. Bargaining after setting prices

As done previously, the ISP and the CPs will choose their respective prices knowing that the revenue they will get is the outcome of bargaining. We shall present our results for $n = 2$, due to combinatorial complexity reasons.

As in the $n = 1$ case, the ISP and CP i will share $p_i^s + p_i^c + p_i^a$, the revenue coming from internauts accessing content from CP i, in the proportion γ_i and $1-\gamma_i$. One immediate observation is that at equilibrium, this revenue should be nonnegative if demand is strictly positive because otherwise CP i can raise price and force demand to be zero, change his loss to zero, and strictly improve. Another observation is that all utilities and the constraints depend on p_i^s and p_i^c only through the sum $p_i^s+p_i^c$. While this sum is bounded if the demand vector is to be strictly positive, neither p_i^s nor p_i^c need be bounded, and so the action sets for each of the agents is unbounded. We shall present our main result for bargaining after setting prices for $n=2$ and under a condition on the bargaining powers, namely, the matrix H with entries

$$H_{ij}=\begin{cases}\gamma_i & i=j,\\ -(\frac{\beta}{\alpha})\left(\frac{\gamma_i+\gamma_j}{2}\right) & i\neq j,\end{cases} \tag{27}$$

is positive definite. This condition arises to keep the utility of the ISP a concave function of p^s in Region 1.

Proposition 1. *Let $\tau=\beta/\alpha$ and $n=2$. The matrix H is positive definite if and only if*

$$\sqrt{\max\left\{\frac{\gamma_1}{\gamma_2},\frac{\gamma_2}{\gamma_1}\right\}}\leq\frac{1+\sqrt{1-\tau^2}}{\tau}.$$

Under this condition, the Hessian of U_{ISP} in Region 1, given by $-2\alpha H$, is negative definite, and so U_{ISP} is a concave function of (p_1^s,p_2^s) in Region 1.

Proof: H is a 2×2 matrix and the statement is straightforward to verify by direct evaluation of eigenvalues and requiring that they be positive. The expression for U_{ISP} immediately yields that the Hessian is $-2\alpha H$. We omit the details. ■

This condition holds, for example, when the γ_i's are equal and $\alpha>\beta$.

Our main result of this section is the following mixed bag. Recall that the case $\beta=0$ was already considered and disposed; so we shall consider only $\beta>0$.

Theorem 6. *Consider $n=2$. Let the matrix H given by (27) be positive definite. Also let $\alpha>\beta>0$. Without loss of generality, assume $p_1^a\geq p_2^a$. For the case when bargaining is done after setting the prices, the following hold.*

- *If p_1^a is large enough so that*

$$p_1^a\geq(2\alpha/\beta)p_2^a+(2\alpha/\beta-1)D_0, \tag{28}$$

then there exists a pure strategy Nash equilibrium with $d_1>0$ and $d_2=0$. Such an equilibrium satisfies all the properties of a single-CP and single-ISP equilibrium given in Theorem 2 with D_0 and α replaced by $D_0'=D_0(\alpha+\beta)/\alpha$ and $\alpha'=(\alpha^2-\beta^2)/\alpha$. There is no other pure strategy Nash equilibrium.

- *If (28) does not hold, there exists no pure strategy Nash equilibrium.*

Proof: See Appendix D. ■

Thus even though post-arbitration in the single-CP single ISP case always gave a unique Nash equilibrium with the desirable strictly positive demand, the desirable feature disappears when there are multiple CPs, $\alpha>\beta>0$, and p_1^a is not high enough to satisfy (28). In particular, when p_i^a are equal, there is no post-arbitration equilibrium. Pre-arbitration continues to yield a unique Nash equilibrium among those profiles with strictly positive demand vectors. In the case when there is indeed a post-arbitration equilibrium, under (28), CP 2 is shut out by CP 1. The above result corrects an error in [16, Th. 4] where the equilibrium under (28) was missed.

IV. DYNAMICS

In this section we constrain prices to remain in Region 1 of Figure 4. This yields a coupled constraint which is a significant difference with respect to the unconstrained model in Section III. For this new setting, we discuss two dynamic models with multiple content providers. Again, for ease of exposition, we restrict to the case of two CPs.

A. Continuous dynamics

Let us assume that the players set their prices such that the demand from each CP is nonnegative, i.e., (8) is greater than or equal to zero for both CPs. This imposes coupled constraints on the set of prices $(p^s,p^c)\in\mathbb{R}^4$ given by

$$\begin{aligned} d_1(p^s,p^c)&\geq0, & d_2(p^s,p^c)&\geq0,\\ p_1^s+p_1^d&\geq0, & p_2^s+p_2^d&\geq0,\\ p_1^c-p_1^d+p_1^a&\geq0, & p_2^c-p_2^d+p_2^a&\geq0.\end{aligned}$$

Let R denote the set of prices that satisfy these constraints. It is easy to verify that the above constraints also result in the following upper bounds on the prices:

$$\begin{aligned} p_1^s&\leq\tfrac{D_0}{\alpha-\beta}+p_1^a-p_1^d, & p_2^s&\leq\frac{D_0}{\alpha-\beta}+p_2^a-p_2^d\\ p_1^c&\leq\tfrac{D_0}{\alpha-\beta}+p_1^d, & p_2^c&\leq\frac{D_0}{\alpha-\beta}+p_2^d,\end{aligned}$$

and thus the set R is compact. Furthermore, due to the linearity of the constraints in the prices, R is convex. As argued in Section III, for any price vector $p=(p^s,p^c)\in R$, the mappings $U_{\mathsf{ISP}}(\cdot,p^c),U_{\mathsf{CP},1}(p^s,\cdot,p_2^c)$ and $U_{\mathsf{CP},1}(p^s,p_1^c,\cdot)$ are concave functions in the "$\cdot$" variables.

Given the concave utility functions defined on the coupled constraint set R, we are in the setting of n-person concave games studied by Rosen [17]. We can then directly use the dynamic model proposed by Rosen [17, Sec. 4]. In our game setting the system of differential equations for the strategies p_1^s,p_2^s,p_1^c,p_2^c is:

$$\frac{\mathrm{d}p_1^s}{\mathrm{dt}}=\frac{\partial U_{\mathsf{ISP}}(p^s,p^c)}{\partial p_1^s}+u_1(p)\frac{\partial d_1(p)}{\partial p_1^s}+u_2(p)\frac{\partial d_2(p)}{\partial p_1^s}+u_3(p)$$

$$\frac{\mathrm{d}p_2^s}{\mathrm{dt}}=\frac{\partial U_{\mathsf{ISP}}(p^s,p^c)}{\partial p_2^s}+u_1(p)\frac{\partial d_1(p)}{\partial p_2^s}+u_2(p)\frac{\partial d_2(p)}{\partial p_2^s}+u_4(p)$$

$$\frac{\mathrm{d}p_1^c}{\mathrm{dt}}=\frac{\partial U_{\mathsf{CP},1}(p^s,p^c)}{\partial p_1^c}+u_1(p)\frac{\partial d_1(p)}{\partial p_1^c}+u_2(p)\frac{\partial d_2(p)}{\partial p_1^c}+u_5(p)$$

$$\frac{\mathrm{d}p_2^c}{\mathrm{dt}}=\frac{\partial U_{\mathsf{CP},2}(p^s,p^c)}{\partial p_2^c}+u_1(p)\frac{\partial d_1(p)}{\partial p_2^c}+u_2(p)\frac{\partial d_2(p)}{\partial p_2^c}+u_6(p).$$

In the above dynamics it is assumed that a central agent computes $u(p)=(u_1(p),\ldots,u_6(p))$ as in [17, eqn. (4.5)] and communicates the values to the players. The above dynamics tend to an equilibrium as is established next.

Theorem 7. *Let $\alpha > \beta$. Starting from any point $p \in R$, the continuous solution $p(t)$ to the above system of differential equations remains in R for all t and converges to the unique equilibrium point.*

Proof: The first claim follows directly from Rosen's [17, Th. 7]. To prove the second part, we verify the so-called *diagonal strict concavity* property of

$$\sigma(p) = U_{\mathsf{ISP}}(p) + U_{\mathsf{CP},1}(p) + U_{\mathsf{CP},2}(p), \quad p \in R.$$

Let $g(p)$ denote the gradient of $\sigma(p)$ given by

$$g(p) = \begin{bmatrix} \partial U_{\mathsf{ISP}}(p)/\partial p_1^s \\ \partial U_{\mathsf{ISP}}(p)/\partial p_2^s \\ \partial U_{\mathsf{CP},1}(p)/\partial p_1^c \\ \partial U_{\mathsf{CP},2}(p)/\partial p_2^c \end{bmatrix}.$$

With $\tau := \beta/\alpha$, the Jacobian $G(p)$ of the above matrix can be verified to be the symmetric matrix

$$G(p) = -\alpha \begin{bmatrix} 2 & -2\tau & 1 & -\tau \\ -2\tau & 2 & -\tau & 1 \\ 1 & -\tau & 2 & -\tau \\ -\tau & 1 & -\tau & 2 \end{bmatrix}.$$

It is easy to see that the eigenvalues of $-G(p)/\alpha$ are

$$((3\tau+4) \pm \sqrt{(3\tau+4)^2 - 4(\tau^2+4\tau+3)})/2$$
$$((4-3\tau) \pm \sqrt{(4-3\tau)^2 - 4(\tau^2-4\tau+3)})/2,$$

and that these eigenvalues are strictly positive for $\tau \in [0, 1)$. $G(p)$ is therefore negative definite. By [17, Th. 6], $\sigma(p)$ is diagonally strictly concave, and by [17, Th. 9], the equilibrium point is globally asymptotically stable for the system of differential equations; this establishes convergence. ∎

B. Discrete dynamics

In this subsection we study discrete dynamics motivated by the best response dynamics. We assume the providers set their price, say, at the beginning of each day, as the best response to prices set by the other players on the previous day.

Let $p_t = ((p_{1t}^s, p_{2t}^s), p_{1t}^c, p_{2t}^c)$ denote the price set by the players on day t. Recalling the concavity properties of the utility functions, the price set by the players on day $m = t+1$ are obtained by setting

$$\partial U_{\mathsf{ISP}}((p_{1m}^s, p_{2m}^s), p_{1t}^c, p_{2t}^c)/\partial p_1^s = 0 \tag{29}$$
$$\partial U_{\mathsf{ISP}}((p_{1m}^s, p_{2m}^s), p_{1t}^c, p_{2t}^c)/\partial p_2^s = 0 \tag{30}$$
$$\partial U_{\mathsf{CP},1}((p_{1t}^s, p_{2t}^s), p_{1m}^c, p_{2t}^c)/\partial p_1^c = 0 \tag{31}$$
$$\partial U_{\mathsf{CP},2}((p_{1t}^s, p_{2t}^s), p_{1t}^c, p_{2m}^c)/\partial p_2^s = 0. \tag{32}$$

The ISP controls the price (p_{1m}^s, p_{2m}^s) and sets them so that both (29) and (30) are simultaneously satisfied. The above conditions straightforwardly result in the following equations:

$$2\alpha p_{1m}^s - 2\beta p_{2m}^s = D_0 - \alpha p_{1t}^c + \beta p_{2t}^c - \alpha p_1^d + \beta p_2^d$$
$$2\alpha p_{2m}^s - 2\beta p_{1m}^s = D_0 - \alpha p_{2t}^c + \beta p_{1t}^c - \alpha p_2^d + \beta p_1^d$$
$$2\alpha p_{1m}^c = D_0 - \alpha p_{1t}^s + \beta p_{2t}^s + \beta p_{2t}^c - \alpha(p_1^a - p_1^d)$$
$$2\alpha p_{2m}^c = D_0 - \alpha p_{2t}^s + \beta p_{1t}^s + \beta p_{1t}^c - \alpha(p_2^a - p_2^d).$$

This is a linear mapping that can be compactly written in the matrix form as

$$p_{t+1}^T = X p_t^T + Y \tag{33}$$

where, with $\tau = \beta/\alpha$, we take

$$X = \frac{1}{2} \begin{bmatrix} 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \\ -1 & \tau & 0 & \tau \\ \tau & -1 & \tau & 0 \end{bmatrix}, Y = \begin{bmatrix} \frac{D_0 - (\alpha-\beta)p_1^d}{2(\alpha-\beta)} \\ \frac{D_0 - (\alpha-\beta)p_2^d}{2(\alpha-\beta)} \\ \frac{D_0 - \alpha(p_1^a - p_1^d)}{2\alpha} \\ \frac{D_0 - \alpha(p_2^a - p_2^d)}{2\alpha} \end{bmatrix}.$$

An easy guess of the fixed point to the iteration in (33) is

$$p_{\mathsf{opt}}^T = (I - X)^{-1} Y. \tag{34}$$

Under the assumptions of Theorem 3 for two CPs ($n = 2$), it can be verified that p_{opt}^T is the solution of that theorem given in (36). Under the same assumptions, the dynamics converge to that solution, as guaranteed next.

Theorem 8. *For $\tau \in [0, 1)$, the dynamics given in (33) converges to the fixed point $p_{\mathsf{opt}}^T = (I - X)^{-1} Y$.*

Proof: The eigenvalues of the matrix X can be straightforwardly evaluated; they are

$$\frac{\frac{\tau}{2} \pm \sqrt{(\frac{\tau}{2})^2 + 1 - \tau}}{2} \quad \text{and} \quad \frac{-\frac{\tau}{2} \pm \sqrt{(\frac{\tau}{2})^2 - 1 - \tau}}{2}.$$

For $\tau \in [0, 1)$, these eigenvalues are nonzero, of magnitudes strictly smaller than 1, distinct, and hence X is diagonalizable in the form $X = UDU^{-1}$, where D is the diagonal matrix of eigenvalues and U is an invertible matrix. X is also invertible. Consequently, p_{opt}^T in (34) is well-defined and satisfies

$$p_{\mathsf{opt}}^T = X p_{\mathsf{opt}}^T + Y.$$

Using this and (33), with p_0^T as the initial iterate, the norm of the error at iteration $t+1$ telescopes as

$$\begin{aligned} ||p_{t+1}^T - p_{\mathsf{opt}}^T|| &= ||X(p_t^T - p_{\mathsf{opt}}^T)|| \\ &= ||X^{t+1}(p_0^T - p_{\mathsf{opt}}^T)|| \\ &= ||(UDU^{-1})^{t+1}(p_0^T - p_{\mathsf{opt}}^T)|| \\ &= ||UD^{t+1}U^{-1}(p_0^T - p_{\mathsf{opt}}^T)||. \end{aligned}$$

Since the magnitudes of the eigenvalues are strictly less than 1, the error vector converges to 0 exponentially quickly in the number of iterations. ∎

Remarks: 1) The iterates converge if $\tau = \beta/\alpha < 1$. However, to guarantee that the solution is in R, we need the other necessary and sufficient condition $(A + 2\alpha I_n)^{-1}[D_0 E_n + A p^a]$ to be made of strictly positive entries.

2) Even if these hold, the iterates may not remain in R due to the coupled nature of the constraints. Strictly speaking then, the dynamics is not the best response dynamics. Indeed, with $D_0 = 200, \alpha = 6, \beta = 3, p_1^d = 10, p_2^d = 25, p_1^a = 45, p_2^a = 10$, it can be see that with $p_0 = (19, 2, 25, 28)$ when demand for both contents is positive, we get $p_1 = (15.8333, 6.8333, -2.8333, 34.1667)$ where demand for CP 1 content alone is positive. Nevertheless, the iterates converge to the unique equilibrium with strictly positive demands.

V. DISCUSSION

In this paper, we studied a model of a nonneutral network and investigated the role of bargaining power in identifying side payments. We began with the simple case of a single CP and a single ISP and studied the equilibria when they bargained with each other over the side payment. The bargaining could happen either before they set their prices or afterward. The relative bargaining power of the ISP with respect to the CP was captured by a single real number between 0 and 1. We highlighted several interesting features of the equilibria. If the agents bargain beforehand, there can be zero-demand equilibria, but there is one unique desirable equilibrium with strictly positive demand. The actual amount of the payment that they agree upon is inconsequential to the users, but the mere fact that they agree upon it before-hand (via bargaining) is beneficial to all agents. If the agents bargain afterward, the agents share the revenue in proportion of their bargaining powers. There is a unique equilibrium and it has the desirable feature of a strictly positive demand.

When there are multiple CPs and demand for content i depends only on the content i's price (sum of CP price and ISP price), then the problem reduces to n separable single-CP single-ISP problems. If the demand for content i is positively correlated with pricing of other contents, then for pre-bargaining, the results are qualitatively similar to the single-CP single-ISP case. We demonstrated that there is exactly one unique equilibrium that has strictly positive demand for all contents, and this holds if and only if a certain condition on the payments holds. For post-bargaining, however, no equilibrium exists unless the advertisement revenues widely differ. This is in contrast to the single-CP single-ISP case.

Our model is, needless to say, a mere caricature that captures certain types of interactions between ISPs, CPs, and internauts. The biggest benefit is that it is tractable, as evidenced by the obtained expressions in this paper. The litmus test of its usefulness will be its ability, or otherwise, to explain some observed behavior, even if only qualitatively. Studies in this direction are ongoing. Finally, aspects of (1) investment in infrastructure by the CPs and the ISPs and (2) collusion between some CPs and the ISP should be brought in to enrich the model. The latter was briefly considered in [16]. We hope to pursue some of these in future works.

APPENDIX A
PROOF OF THEOREM 3

Consider a fixed p^d. We shall only focus on strategies jointly constrained so that $d_i > 0$ for all i. The joint constraint on p^s and p^c is given by (9), and the demands are given by (8). Let us look at U_{ISP} as a function of p^s and $U_{\mathsf{CP},i}$ as a function p^c_i. We already saw that the former is concave since $\alpha > (n-1)\beta$. Inspection of the expression for $U_{\mathsf{CP},i}$ shows that it is also quadratic and strictly concave in p^c_i. Since we seek equilibria with strictly positive demand, such equilibria are interior points of, for example in case of $n = 2$, Region 1 in Figure 4. It is therefore necessary that first order optimality conditions hold for such equilibria. So, setting the gradient of U_{ISP} with respect to p^s to zero, we get

$$\begin{aligned}\frac{\partial U_{\mathsf{ISP}}}{\partial p^s_k} &= \sum_{j:j\neq k} \beta(p^s_j + p^d_j) - \alpha(p^s_k + p^d_k) \\ &\quad + D_0 - \alpha(p^s_k + p^c_k) + \beta \sum_{j:j\neq k} (p^s_j + p^c_j) = 0\end{aligned}$$

for each k. Similarly, setting each $\partial U_{\mathsf{CP},k}/\partial p^c_k = 0$ yields

$$D_0 - \alpha(p^s_k + p^c_k) + \beta \sum_{j:j\neq k} (p^s_j + p^c_j) - \alpha(p^c_k + p^a_k - p^d_k) = 0$$

for each k. We next write these $2n$ equations in matrix notation. For this purpose recall that the matrix $A = (\alpha+\beta)I_n - \beta J_n$, where all diagonal elements are α and all off-diagonal elements are $-\beta$, and define $B = (\alpha + \beta/2)I_n - (\beta/2)J_n$, where all diagonal elements are α and all off-diagonal elements are $-\beta/2$. Also recall that E_n is the vector of size $n \times 1$ with all-one entries. Then the above equations become:

$$\begin{bmatrix} 2A & A \\ A & 2B \end{bmatrix} \begin{bmatrix} p^s \\ p^c \end{bmatrix} = \begin{bmatrix} -A & \bigcirc \\ \alpha I_n & -\alpha I_n \end{bmatrix} \begin{bmatrix} p^d \\ p^a \end{bmatrix} + D_0 E_{2n}. \tag{35}$$

The matrices A and B commute because both are linear combinations of the commuting matrices I_n and J_n. Moreover, the determinant of the matrix on the left side is

$$\begin{aligned}\det(4AB - A^2) &= \det(A(A + 2\alpha I_n)) \\ &= \det(A)\det(A + 2\alpha I_n) \\ &= (\alpha+\beta)^{n-1}(\alpha - (n-1)\beta) \\ &\qquad \cdot(3\alpha+\beta)^{n-1}(3\alpha - (n-1)\beta) \\ &> 0.\end{aligned}$$

This follows because the eigenvalues of the matrix

$$M(\rho) = (1-\rho)I_n + \rho J_n$$

are $1-\rho$ repeated $n-1$ times and $1+(n-1)\rho$ occurring once. The matrices A and $A + 2\alpha I_n$ are scaled versions of $M(\rho)$ with appropriate choices for ρ. Thus the matrix on the left side of (35) is invertible. From the fact that A and B commute, the fact that $4AB - A^2 = A(A + 2\alpha I_n)$, and the formula for the inverse of two-by-two block matrices with commutable entries, one writes by inspection that

$$\begin{bmatrix} 2A & A \\ A & 2B \end{bmatrix}^{-1} = (A(A + 2\alpha I_n))^{-1} \circ \begin{bmatrix} 2B & -A \\ -A & 2A \end{bmatrix},$$

where the symbol "$\circ$" implies that the matrix before it left-multiplies all the elements of the bigger matrix following it. Multiplying (35) by the above inverse, and observing that $2B + \alpha I_n = A + 2\alpha I_n$, we get

$$\begin{aligned}\begin{bmatrix} p^s \\ p^c \end{bmatrix} &= \begin{bmatrix} -I_n & \alpha(A + 2\alpha I_n)^{-1} \\ I_n & -2\alpha(A + 2\alpha I_n)^{-1} \end{bmatrix} \begin{bmatrix} p^d \\ p^a \end{bmatrix} \\ &\quad + D_0 \begin{bmatrix} \alpha(A(A + 2\alpha I_n))^{-1}E_n \\ (A + 2\alpha I_n)^{-1}E_n \end{bmatrix}.\end{aligned} \tag{36}$$

Let us now verify that the revenues to each of CPs and the ISP are nonnegative. First we handle the ISP. Observe that the components of $p^s + p^d$ constitute revenues from each family of internauts. From (36) we gather that

$$\begin{aligned} p^s + p^d &= \alpha(A + 2\alpha I_n)^{-1} p^a + \alpha D_0 (A + 2\alpha I_n)^{-1} A^{-1} E_n \\ &= \alpha A^{-1} (A + 2\alpha I_n)^{-1} (A p^a + D_0 E_n). \qquad (37) \end{aligned}$$

Next, consider the CPs. Again from (36) we gather that

$$\begin{aligned} p^c - p^d + p^a &= (I_n - 2\alpha(A + 2\alpha I_n)^{-1}) p^a \\ &\quad + D_0 (A + 2\alpha I_n)^{-1} E_n \\ &= (A + 2\alpha I_n)^{-1} (A p^a + D_0 E_n). \qquad (38) \end{aligned}$$

From (36), it also follows that

$$p^s + p^c = (A + 2\alpha I_n)^{-1} (-\alpha p^a + D_0 (I_n + \alpha A^{-1}) E_n)$$

so that the demand vector $d = D_0 E_n - A(p^s + p^c)$ can be written (after observing that all involved matrices commute) as

$$d = \alpha (A + 2\alpha I_n)^{-1} (A p^a + D_0 E_n). \qquad (39)$$

Using this in (37), we see that $p^s + p^d = A^{-1} d$ so that

$$U_{\mathsf{ISP}} = d^T A^{-1} d. \qquad (40)$$

Necessity of

$$(A + 2\alpha I_n)^{-1} (A p^a + D_0 E_n) > 0 \qquad (41)$$

is then clear from (38) and (39). Indeed, if any component on the left-hand side of (41) is nonpositive, the corresponding CP derives a nonpositive revenue per unit demand, and the demand for this CP's content truncates to 0. Such a point is either not an equilibrium, or if so, not all demands are strictly positive.

Sufficiency of (41) is obtained as follows. If (41) holds, then (38), (39), and (40) yield a point with strictly positive revenue for all agents and strictly positive demand. Indeed, from (38), revenue per unit demand is strictly positive for all CPs; from (39), all demands are strictly positive and consequently, all CPs' utilities are strictly positive; from (40) and the fact that A^{-1} has strictly positive eigenvalues, the ISP revenue is also positive. Furthermore, this point satisfies first-order optimality conditions. Given the concavity of the utility functions, it is a Nash equilibrium.

We have thus established that (41) is necessary and sufficient for a pure strategy Nash equilibrium to exist. When this holds, the pure strategy Nash equilibria are such that (37)-(40) hold, for a given p^d.

Let us now bring bargaining into the picture. Since the choice of p^d does not affect the demands $d_i(p^s + p^d)$ as in (39), and the collections per unit demand by each of the CPs and the ISP are as in (38) and (37), respectively, the optimal solution p^d to the bargaining problem can be taken as any vector.

It then follows that the unique demand is given by (39) which establishes the fourth bullet. The form of the solution for p^s and p^c in (36) shows that $p^s_i = g_i - p^d_i$ and $p^c_i = h_i + p^d_i$ which verifies the second and the third bullets. Notice that p^d can be any vector, and so the solution is unique up to a free choice of p^d, and the statement of the first bullet is verified. The last bullet follows from the observation that the demand vector, the price charged by the CPs in (38), and the the revenue of the ISP in (40) do not depend on p^d. This concludes the proof. ■

APPENDIX B
PROOF OF THEOREM 4

We first prove the necessity of these conditions. Let (p^s, p^c) be an equilibrium with all demands being zero; it must be the case that (12) is violated, and so

$$p^s + p^c \geq \left(\frac{D_0}{\alpha - (n-1)\beta} \right) E_n.$$

CP i should not be able to reduce his price, increase demand d_i to a strictly positive value, and derive a strictly positive utility. It must therefore be the case that even the least reduced price q^c_i that keeps the demand d_i on the threshold of positivity is too low a price bringing him a negative revenue. More precisely, a price

$$q^c_i + p^s_i = \frac{D_0}{\alpha - (n-1)\beta} \qquad (42)$$

when demand for CP i content is on the threshold of positivity should imply

$$q^c_i - p^d_i + p^a_i \leq 0, \qquad (43)$$

a negative revenue per unit demand for CP i. Substitution of (42) in (43) yields necessity of (21).

We next verify necessity of (22) by contraposition. Let i be a content index for which (22) does not hold, and so

$$p^c_i - p^d_i < D_0 / (\alpha - (n-1)\beta). \qquad (44)$$

Take

$$\varepsilon = \frac{1}{2} \left(\frac{D_0}{\alpha - (n-1)\beta} - (p^c_i - p^d_i) \right) > 0, \qquad (45)$$

and set q^s_i so that $q^s_i + p^d_i = \varepsilon > 0$, i.e., the ISP revenue from CP i content is $\varepsilon > 0$. Also set all other p^s_j for $j \neq i$ to high values so that demand for these other contents is zero. Demand d_i for CP i content is however strictly positive because, by using $\varepsilon = q^s_i + p^d_i$, (44) and (45), we get

$$\begin{aligned} q^s_i + p^c_i &= (q^s_i + p^d_i) - p^d_i \\ &= \varepsilon + p^c_i - p^d_i \\ &= \frac{1}{2} \left(\frac{D_0}{\alpha - (n-1)\beta} - (p^c_i - p^d_i) \right) + (p^c_i - p^d_i) \\ &< \frac{D_0}{\alpha - (n-1)\beta}. \end{aligned}$$

Thus (12) holds, and so $d_i > 0$. (All other demands are zero). The ISP now has a strictly positive utility, and the profile cannot be a Nash equilibrium. By contraposition, necessity of (22) is established.

We now argue sufficiency of (21) and (22). Take a profile that satisfies these conditions. A glance at the proof of necessity of (21) indicates that there is no deviation for CP i to derive a positive utility. To see that there is no deviation for the ISP that will yield a positive revenue, let q^s be any vector of ISP prices. Without loss of generality, reorder the prices

$q_i = q_i^s + p_i^c$, $i = 1, 2, \ldots, n$, so that $q_1 \le q_2 \le \cdots \le q_n$. If ISP revenue for content j were strictly positive, then

$$0 < q_j^s + p_j^d \le q_j^s + p_j^c - \frac{D_0}{\alpha - (n-1)\beta}$$

where the second inequality follows from (22), and so

$$q_j = q_j^s + p_j^c > \frac{D_0}{\alpha - (n-1)\beta} = T(1) \tag{46}$$

for any such j with strictly positive ISP revenue for content j. ($T(1)$ is defined in (12)). However, from (17) and (16), any index with strictly positive demand satisfies $q_i < T(i) \le T(1)$. Comparing this with (46), we deduce that indices with strictly positive demand have nonpositive revenue per unit demand. The ISP revenue is therefore nonpositive, and there is no deviation that will yield a better revenue. This proves sufficiency of the stated conditions, and the characterization of all Nash equilibria with all demands being zero is complete. ■

APPENDIX C
PROOF OF THEOREM 5

We shall prove only (a). Proof of (b) is similar and is omitted.

We first prove necessity of the stated conditions. Let $((p_1^s, p_2^s), p_1^c, p_2^c)$ be an equilibrium with $d_1 > 0$ and $d_2 = 0$. Then, from the discussion on demands, we must have

$$\begin{aligned} p_1 &= p_1^s + p_1^c < \frac{D_0}{\alpha - \beta} \\ p_2 &= p_2^s + p_2^c \ge \frac{D_0 + \beta p_1}{\alpha}. \end{aligned} \tag{47}$$

Necessity of (26) is immediate from (47).

We next prove the necessity of (25). Since $d_2 = 0$, the current utility for CP 2 is zero. No unilateral deviation of CP 2 should yield him a strictly positive utility. For a strictly positive utility, he must reduce his price to make the demand for his content strictly positive. But even the least reduction in his price that puts the demand for his content on the threshold of positivity, a price q_2^c such that $q_2^c + p_2^s = (D_0 + \beta p_1)/\alpha$ should already yield him a net nonpositive revenue $q_2^c + p_2^a - p_2^d \le 0$. Substitution of the former equality in the latter inequality yields (25) as a necessary condition.

We now consider deviations of the ISP. We first observe that ISP's utility must be nonnegative. Next, given that the price profile falls in Region 4 of Figure 4, the ISP can reduce the price of p_2^s to q_2^s such that

$$q_2 = q_2^s + p_2^c = T(2) = \frac{D_0 + \beta p_1}{\alpha} \tag{48}$$

without affecting the demand d_1 and keeping the demand $d_2 = 0$. His revenue does not change, and the price profile (p_1, q_2) is now on the line BO in Figure 4. The ISP's utility is thus

$$\begin{aligned} U_{\mathsf{ISP}}(p_1, p_2) &= U_{\mathsf{ISP}}(p_1, q_2) \\ &= (D_0 - \alpha p_1 + \beta q_2)(p_1^s + p_1^d) \\ &\quad + (D_0 - \alpha q_2 + \beta p_1)(q_2^s + p_2^d) \\ &= (D_0 - \alpha p_1 + \beta q_2)(p_1 - p_1^c + p_1^d) \\ &\quad + (D_0 - \alpha q_2 + \beta p_1)(q_2 - p_2^c + p_2^d). \end{aligned} \tag{49}$$

Let us now consider infinitesimal deviations either into Region 1 or along the line BO, and prove necessity of (23) and (24). The ISP can clearly change p_1^s and q_2^s simultaneously to place the price vector in a neighborhood of (p_1, q_2) inside Region 1 or on the line BO. Such deviations are given by increments $u = (u_1, u_2)$ that satisfy $u_2 \le (\beta/\alpha)u_1$. Since $U_{\mathsf{ISP}}(p_1, q_2)$ given by (49) is differentiable in this region, and there must be no direction pointing into Region 1 in which U_{ISP} increases, we must have the dot-product

$$\nabla U_{\mathsf{ISP}}(p_1, q_2)^T \; u \le 0 \quad \forall u \text{ with } u_2 \le (\beta/\alpha)u_1.$$

It follows that the direction of steepest ascent for U_{ISP} at (p_1, q_2) which is $\nabla U_{\mathsf{ISP}}(p_1, q_2)$ must be normal to the line defined by $u_2 = (\beta/\alpha)u_1$ and pointing away from Region 1, i.e.,

$$\frac{\partial U_{\mathsf{ISP}}}{\partial q_2} = -\frac{\alpha}{\beta}\frac{\partial U_{\mathsf{ISP}}}{\partial p_1}. \tag{50}$$

From (49), and after noting that $r_{\mathsf{ISP},1} := (p_1 - p_1^c + p_1^d)$ and $r_{\mathsf{ISP},2} := (q_2 - p_2^c + p_2^d)$ are the ISP revenues per unit demand arising from contents of CP 1 and CP 2, respectively, we get

$$\frac{\partial U_{\mathsf{ISP}}}{\partial q_2} = \beta r_{\mathsf{ISP},1} + d_2 - \alpha r_{\mathsf{ISP},2} = \beta r_{\mathsf{ISP},1} - \alpha r_{\mathsf{ISP},2}$$

and

$$\frac{\partial U_{\mathsf{ISP}}}{\partial p_1} = \beta r_{\mathsf{ISP},2} + d_1 - \alpha r_{\mathsf{ISP},1}.$$

Substitution of these in (50) yields that the condition

$$d_1 = \alpha' r_{\mathsf{ISP},1} \tag{51}$$

is a necessary condition for direction of increase for the ISP's utility. We now use $d_1 = D_0 - \alpha p_1 + \beta q_2$, the expression for q_2 given in (48), and the definition of $r_{\mathsf{ISP},1}$ and rewrite (51) as

$$D_0' - \alpha'(p_1^s + p_1^c) = \alpha'(p_1^s + p_1^d). \tag{52}$$

Note that this equation fixes p_1^s given a p_1^c:

$$p_1^s = \frac{D_0' - \alpha'(p_1^c + p_1^d)}{2\alpha'}. \tag{53}$$

Furthermore, if we can establish the necessity of (24) which fixes p_1^c, then (52) implies the necessity of (24) as well, as can be verified by direct substitution.

We now establish the necessity of (24). Consider first an interior point of Region 4. Small deviation by CP 1 move the point along the abscissa, and if small enough the deviation keeps the resulting point inside the interior of Region 4. Then d_2 continues to be 0 and $d_1 > 0$. As a consequence, it follows that $d_1 = D_0' - \alpha' p_1$, where $p_1 = p_1^s + p_1^c$ and the variation here is in p_1^c. The revenue for CP 1 is $p_1^c + p_1^a - p_1^d$ so that

$$U_{\mathsf{CP},1} = (D_0' - \alpha'(p_1^s + p_1^c))(p_1^c + p_1^a - p_1^d).$$

It is thus necessary that the first order optimality condition hold, and so

$$\frac{\partial U_{\mathsf{CP},1}}{\partial p_1^c} = (D_0' - \alpha'(p_1^s + p_1^c)) - \alpha'(p_1^c + p_1^a - p_1^d) = 0 \tag{54}$$

so that

$$(D_0' - \alpha'(p_1^s + p_1^c)) = \alpha'(p_1^c + p_1^a - p_1^d). \tag{55}$$

Solving the simultaneous equations (52) and (55), we get the necessity of (23) and (24) among interior points of Region 4.

Now consider points on the line BO. Let us denote the right-hand sides of (23) and (24) as $p^s_{1,\mathsf{opt}}$ and $p^c_{1,\mathsf{opt}}$, respectively, i.e.,

$$\begin{aligned} p^s_{1,\mathsf{opt}} &= \frac{D'_0 + \alpha' p^a_1}{3\alpha'} - p^d_1 && (56) \\ p^c_{1,\mathsf{opt}} &= \frac{D'_0 - 2\alpha' p^a_1}{3\alpha'} + p^d_1 && (57) \end{aligned}$$

If $p^c_1 \geq p^c_{1,\mathsf{opt}}$, consider an infinitesimal decrease in p^c_1 which puts the point in the interior of Region 4. The left partial derivative is

$$\frac{\partial^- U_{\mathsf{CP},1}}{\partial p^c_1} = (D'_0 - \alpha'(p^s_1 + p^c_1)) - \alpha'(p^c_1 + p^a_1 - p^d_1), \quad (58)$$

the right-hand side of (54). We then have the following chain of equalities:

$$\begin{aligned} &\frac{\partial^- U_{\mathsf{CP},1}}{\partial p^c_1} \\ &= (D'_0 - \alpha'(p^s_1 + p^c_1)) - \alpha'(p^c_1 + p^a_1 - p^d_1) \\ &= (D'_0 - \alpha'(p^s_{1,\mathsf{opt}} + p^c_{1,\mathsf{opt}})) - \alpha'(p^c_{1,\mathsf{opt}} + p^a_1 - p^d_1) \\ &\quad + \alpha'(p^s_{1,\mathsf{opt}} - p^s_1) + 2\alpha'(p^c_{1,\mathsf{opt}} - p^c_1) && (59) \\ &= 0 - (1/2)\alpha'(p^c_{1,\mathsf{opt}} - p^c_1) + 2\alpha'(p^c_{1,\mathsf{opt}} - p^c_1) && (60) \\ &= (3/2)\alpha'(p^c_{1,\mathsf{opt}} - p^c_1), && (61) \end{aligned}$$

where (59) follows by adding and subtracting

$$(D'_0 - \alpha'(p^s_{1,\mathsf{opt}} + p^c_{1,\mathsf{opt}})) - \alpha'(p^c_{1,\mathsf{opt}} + p^a_1 - p^d_1).$$

Equation (60) follows because (55) and (52) hold for the pair $(p^c_{1,\mathsf{opt}}, p^s_{1,\mathsf{opt}})$, and from (53) we see that

$$p^s_1 - p^s_{1,\mathsf{opt}} = -(1/2)(p^c_1 - p^c_{1,\mathsf{opt}}).$$

From (61), $p^c_1 > p^c_{1,\mathsf{opt}}$ implies that an infinitesimal decrease results in a strict increase for CP 1. It must therefore be that $p^c_1 \leq p^c_{1,\mathsf{opt}}$ for the profile under consideration to be an equilibrium.

When $p^c_1 \leq p^c_{1,\mathsf{opt}}$, consider an infinitesimal increase in p^c_1 which puts the point in the interior of Region 1, i.e., both d_1 and d_2 become positive. As a consequence, the right-derivative is now

$$\frac{\partial^+ U_{\mathsf{CP},1}}{\partial p^c_1} = (D'_0 - \alpha'(p^s_1 + p^c_1)) - \alpha(p^c_1 + p^a_1 - p^d_1); \quad (62)$$

observe that the difference with (58) is that the second term is multiplied only by α instead of α' as now both CPs have positive demand upon deviation in Region 1. Following the same steps leading to (61), we now get

$$\begin{aligned} &\frac{\partial^+ U_{\mathsf{CP},1}}{\partial p^c_1} \\ &= 0 - (1/2)\alpha'(p^c_{1,\mathsf{opt}} - p^c_1) + (\alpha' + \alpha)(p^c_{1,\mathsf{opt}} - p^c_1) \\ &= (\alpha + \alpha'/2)(p^c_{1,\mathsf{opt}} - p^c_1) \end{aligned}$$

and now the right-hand side has a different scale when compared with (61). When $p^c_1 < p^c_{1,\mathsf{opt}}$, we have $\frac{\partial^+ U_{\mathsf{CP},1}}{\partial p^c_1} > 0$ yielding a strict increase in CP 1 utility. It follows that we must have $p^c_1 = p^c_{1,\mathsf{opt}}$. This establishes the necessity of (24), and the proof of necessity is complete.

Next, to address sufficiency of the stated conditions, consider a profile satisfying them. Our necessity argument for (25) also shows that CP 2 has no deviation yielding him a strictly positive utility. For the ISP, the necessity argument considered an equivalent point on the line BO, and showed that there are no infinitesimal deviations around this point that will yield a better utility. But on account of concavity of the utility functions, no other point in Region 1 (including the boundary AO) will yield a strictly better utility. Since the boundary AO has also been considered, and the any point in Region 3 yields him the same utility as the point on the line AO with the same ordinate, no point in Region 3 will yield a better utility. Similarly, on account of concavity, CP 1 too as no deviation (infinitesimal or otherwise) that will yield him a strictly better utility. This concludes the proof of sufficiency. ■

APPENDIX D
PROOF OF THEOREM 6

The system has two CPs, $n = 2$. When $\beta = 0$, the problem separates into two smaller problems each with one CP and one ISP, and Theorem 2 applies. We now assume $\alpha > \beta > 0$. It will be useful to recall Figure 4 which has four regions.

1. We now argue there are no pure strategy equilibria in Region 2. This is the region with both demands zero. Let the ISP prices p^s_1, p^s_2 and the CP prices p^c_1 and p^c_2 be such that

$$\begin{aligned} p_1 &= p^s_1 + p^c_1 \geq D_0/(\alpha - \beta) \\ p_2 &= p^s_2 + p^c_2 \geq D_0/(\alpha - \beta). \end{aligned}$$

Consider the point O in Figure 4 given by $(D_0/(\alpha - \beta), D_0/(\alpha - \beta))$. ISP can bring down both his prices to move the price point to O, and demand and revenue collected remain zero. Now consider further deviation along the line BO. To realise this, ISP reduces both prices so that the net price denoted (q_1, q_2) satisfies the equation $q_2 = (D_0 + \beta q_1)/\alpha$. Along this line $d_1 = D'_0 - \alpha' q_1 > 0$ and $d_2 = 0$, where D'_0 and α' are given in the statement of the theorem. But this puts us in a single-CP single-ISP case. By the last part of the proof of Theorem 2, we see that the ISP has a deviation that yields a strictly positive revenue for itself. So no point in Region 2 can be a pure strategy equilibrium.

2. We now argue that no point in the interior of Region 1 can be an equilibrium. Let the prices be such that the total prices on the internauts is (p_1, p_2), a point in Region 1. In this case

$$\begin{aligned} d_1(p_1, p_2) &= D_0 - \alpha p_1 + \beta p_2 > 0 \\ d_2(p_1, p_2) &= D_0 - \alpha p_2 + \beta p_1 > 0. && (63) \end{aligned}$$

Clearly, the net revenue coming from internauts i is $p_i + p^a_i$, and so

$$\begin{aligned} U_{\mathsf{ISP}} &= d_1(p_1, p_2)\gamma_1(p_1 + p^a_1) + d_2(p_1, p_2)\gamma_2(p_2 + p^a_2) \\ U_{\mathsf{CP},i} &= d_i(p_1, p_2)(1 - \gamma_i)(p_i + p^a_i), \quad i = 1, 2. \end{aligned}$$

Since the utilities depend on p^s_i and p^c_i only through $p_i = p^s_i + p^c_i$, partial derivatives with respect to p^s_i and p^c_i may be obtained by considering partial derivatives with respect to p_i. These are (in Region 1)

$$\begin{aligned}
\frac{\partial U_{\mathsf{CP},i}}{\partial p_i} &= (1-\gamma_i)(d_i(p_1,p_2)-\alpha(p_i+p_i^a)), \quad i=1,2\\
\frac{\partial U_{\mathsf{ISP}}}{\partial p_1} &= \gamma_1(d_1(p_1,p_2)-\alpha(p_1+p_1^a))+\gamma_2\beta(p_2+p_2^a)\\
&= \frac{\gamma_1}{1-\gamma_1}\frac{\partial U_{\mathsf{CP}_1}}{\partial p_1}+\gamma_2\beta(p_2+p_2^a)\\
\frac{\partial U_{\mathsf{ISP}}}{\partial p_2} &= \gamma_2(d_2(p_1,p_2)-\alpha(p_2+p_2^a))+\gamma_1\beta(p_1+p_1^a)\\
&= \frac{\gamma_2}{1-\gamma_2}\frac{\partial U_{\mathsf{CP}_2}}{\partial p_2}+\gamma_1\beta(p_1+p_1^a).
\end{aligned}$$

(In passing, we note that from here, it is but a short step to verify that the Hessian for U_{ISP} with respect to (p_1^s,p_2^s) is $-2\alpha H$). The first order necessary conditions imply that the above partial derivatives are zero, and we immediately deduce that $p_i+p_i^a=0$ for both $i=1,2$, i.e., the revenue for each CP's content is zero. Substitution of these in $\frac{\partial U_{\mathsf{CP}_i}}{\partial p_i}=0$ above yields $d_i=0$ for both $i=1,2$. But this is contrary to the assumption that the point is on the interior of Region 1. So no point in the interior of Region 1 can be an equilibrium.

3. Let us now consider a candidate equilibrium in Region 4, with $p_1<D_0/(\alpha-\beta)$ and $p_2\geq(D_0+\beta p_1)/\alpha$.

Let us consider deviations by the ISP. First, he may reduce p_2^s to q_2^s so that p_2 reduces to $q_2=(D_0+\beta p_1)/\alpha$ so that the resulting point (p_1,q_2) is on the line BO, and d_2 is on the threshold of positivity, but revenue of CP 1, revenue of CP 2 (which is zero), and revenue of the ISP still remain unaffected. ISP can now consider deviations from (p_1,q_2) along the line BO or into Region 1, i.e., along the vector (u_1,u_2) where $u_2\leq(\beta/\alpha)u_1$. For such deviations to be fruitless, $\nabla U_{\mathsf{ISP}}(p_1,q_2)$ must point into Region 4, and must in particular be normal to the line BO, and so (50) should hold, which in the present case yields

$$\begin{aligned}
&\gamma_2 d_2(p_1,q_2)-\alpha\gamma_2(p_2+p_2^a)+\gamma_1\beta(p_1+p_1^a)\\
&\quad=-(\alpha/\beta)(\gamma_1 d_1(p_1,q_2)-\alpha\gamma_1(p_1+p_1^a)+\gamma_2\beta(p_2+p_2^a)).
\end{aligned}$$

After cancelations and after using the fact that $d_2(p_1,q_2)=0$, the above equality simplifies to

$$\begin{aligned}
p_1+p_1^a &= \alpha d_1(p_1,q_2)/(\alpha^2-\beta^2)\\
&= d_1(p_1,q_2)/\alpha' \qquad (64)\\
&= (D_0'-\alpha' p_1)/\alpha',
\end{aligned}$$

solving which we get

$$p_1=\frac{D_0'-\alpha' p_1^a}{2\alpha'}, \qquad (65)$$

the solution for the single-CP and single-ISP case. It is easily verified that the net revenue is $p_1+p_1^a=(D_0'+\alpha' p_1^a)/(2\alpha')>0$ and further, from (64),

$$d_1(p_1,q_2)=\alpha'(p_1+p_1^a)=(D_0'+\alpha' p_1^a)/2>0,$$

as in the single-CP and single-ISP case.

Let us next consider local deviations by CP 1 who can increase or decrease p_1^c and therefore perturb p_1. From the above argument, p_1 must satisfy (65). If (p_1,p_2) is an interior point of Region 4, any deviation by CP 1 effectively moves the point (p_1,q_2), a point that is effectively equivalent to the original (p_1,p_2), along the line BO. It is easy to see, using $q_2=(D_0+\beta p_1)/\alpha$, that

$$\begin{aligned}
\frac{\partial}{\partial p_1}U_{\mathsf{CP},1} &= \frac{\partial}{\partial p_1}(d_1(p_1,q_2)(p_1+p_1^a)(1-\gamma_1))\\
&= \frac{\partial}{\partial p_1}((D_0'-\alpha' p_1)(p_1+p_1^a)(1-\gamma_1))\\
&= (d_1(p_1,q_2)-\alpha'(p_1+p_1^a))(1-\gamma_1)\\
&= 0 \qquad (66)
\end{aligned}$$

where the last equality comes from (64). Thus, when (p_1,p_2) is an interior point of Region 4, CP 1 does not benefit from a local deviation. When (p_1,p_2) is on the line BO, it is just (p_1,q_2). A decrease in p_1 moves the point to the interior of Region 4, and the equivalent point moves lower and left along the line BO. Then the argument leading to (66) holds for the left partial derivative $\frac{\partial^-}{\partial p_1}U_{\mathsf{CP},1}$, and decrease in p_1^c does not yield a gain. On the other hand, an increase in p_1^c increases p_1 and puts the system in the interior of Region 1, and we then have

$$\begin{aligned}
\frac{\partial^+}{\partial p_1}U_{\mathsf{CP},1} &= \frac{\partial}{\partial p_1}(d_1(p_1,q_2)(p_1+p_1^a)(1-\gamma_1))\\
&= \frac{\partial}{\partial p_1}((D_0-\alpha p_1+\beta q_2)(p_1+p_1^a)(1-\gamma_1))\\
&= (d_1(p_1,q_2)-\alpha(p_1+p_1^a))(1-\gamma_1)\\
&= (d_1(p_1,q_2)-\alpha'(p_1+p_1^a))(1-\gamma_1)\\
&\quad+(\alpha'-\alpha)(p_1+p_1^a)(1-\gamma_1)\\
&= (\alpha'-\alpha)(p_1+p_1^a)(1-\gamma_1)\\
&< 0
\end{aligned}$$

where the penultimate equality follows because of (64), and the last inequality follows because $\alpha'<\alpha$, but the other two factors are strictly positive. But this implies an infinitesimal increase in p_1^c yields a strict decrease in his utility. There are thus no utility increasing infinitesimal deviations for CP 1.

Lastly, we consider infinitesimal deviations by CP 2. If $p_2>q_2$, then CP 2 can bring down his price so that p_2 reduces to q_2 without a change in his revenue or without a change in demand for his content. Any further decrease moves the operating point into the interior of Region 1, and renders d_2 strictly positive. For such a deviation to be fruitless, the revenue for CP 2 at the operating point (p_1,q_2) should be nonpositive, i.e.,

$$\begin{aligned}
0 &\geq q_2+p_2^a\\
&= \frac{D_0+\beta p_1}{\alpha}+p_2^a.
\end{aligned}$$

Substitution of (65) and rearrangement yields (28) as a necessary condition for equilibrium. If (28) does not hold, there is no pure strategy Nash equilibrium in Region 4.

4. Consider points in Region 3. An argument analogous to above yields that an analogue of (28), with indices 1 and 2 interchanged, is a necessary condition. But as $p_1^a\geq p_2^a$, such a condition cannot hold, and there is no pure strategy Nash equilibrium in Region 3

It is thus clear that if (28) does not hold, there exists no pure strategy Nash equilibrium. This proves the second statement. If (28) does hold, we saw above that the only possible equilibria, if any, are in Region 4 with p_1 as in (65), and $p_2 \geq (D_0 + \beta p_1)/\alpha$. From the first order conditions, no infinitesimal deviation yields a better revenue for any of the agents. From the facts that

- U_{ISP} is concave in Region 1 by the assumption that H is positive definite,
- $U_{\mathsf{CP},1}$ and $U_{\mathsf{CP},2}$ are strictly concave in Region 1,
- they extend continuously to the boundaries AO and BO from Region 1,
- for each point in Region 4, the utilities are determined by the utilities on an equivalent point on the line BO, and similarly,
- for each point in Region 3, the utilities are determined by the utilities on an equivalent point on the line AO, and finally,
- the utilities earned in Region 2 are zero,

it follows that no deviation, infinitesimal or otherwise, will yield a better revenue for any of the agents. So p_1 given in (65) and $p_2 \geq (D_0 + \beta p_1)/\alpha$ characterize the pure strategy Nash equilibrium. This concludes the proof of the theorem.
